# De Morgan's Laws

- $\bullet \ \overline{AB} = \overline{A} + \overline{B}$
- A + B = (A)(B)

### Silicon

- Si
- P-type:
- \* doped with material to remove electrons (add electron holes), usually Boron (B), Aluminum (Al), or Gallium (Ga)
- N-type:
- \* doped with material to add electrons, usually Antimony (Sb), Arsenic (As), or Phosphorous (P)
- Silicon dioxide: SiO<sub>2</sub>
- Polysilicon is just silicon without the crystal structure

# **Transistors**

- nMOS
- \* no bubble
- \* on when input is on, off when input is off
- \* base (of whole chip) is p-substrate
- \* spot of n+ for source and drain, joined by a small layer of oxide  $(SiO_2)$  and polysilicon (gate). also has a spot of p+ (base) connected to ground
- pMOS:
- \* has the bubble
- \* on when input is 0, off when input is 1
- \* whole thing sits in an n-well (inside the p-substrate
- \* source and drain are spots of p+ connected by gate. Gate is polysilicon layer separated from rest of chip by thin layer of SiO<sub>2</sub> on bottom. Also has a n+ spot for base (connected to VDD)
- CMOS: when you combine a nMOS and pMOS network together to make a gate, where one is the compliment of the other
- $V_t$ : Threshold voltage. Nominal voltage below which the transistor is off
- \* below as in closer to 0, not less
- \*  $V_t > 0$  for nMOS,  $V_t < 0$  for pMOS
- \* this is compared to the gate to source voltage,  $V_{as}$
- regions: (for nMOS)
- \* accumulation: gate is negatively charged, attracts positive voids in p-substrate, which block flow in the
- \* depletion: small positive charge on gate repels positive voids from channel, forming a depletion below the gate
- \* inversion: higher positive charge (>  $V_t$ ) is applied to gate, attracting electrons to the channel and allowing

flow

# D Flip Flop vs Latch

- latch is level triggered
- flip flop is edge triggered

#### Fabrication

- n-well: use diffusion or ion implantation
- positive lithography: expose to UV where you want to remove material
- negative lithography: expose to UV where you want to keep material

## Stick Diagram vs Boolean Function

- there is more than one way of making a stick diagram for an expression
- \* stuff in series could be in different order, for instance
- if you do it manually, you need to check it with tools:
- \* LVS: Layout Vs Schematic
- \* DRC: Design Re-Check
- \* These aren't really needed for designs automatically generated from verilog code, because of course that's correct

# Lithography

- the process of printing onto a chip at nanometer scale
- generally uses UV light, wavelength around 150nm
- \* must use fancy tricks to make 10nm features with 150nm light
- \* would be nice to use even lower wavelength X-rays, but those are hard to focus
- negative lithography: use the lithography mask to cover what you want to keep.
- positive lithography: mask what you want to remove
- a lens is used to focus the light
  - \* ideally, want a point source for the light, but that is not practical
  - \* Optical Proximity Effect: what happens when your focus from the lens is not just right
  - \* results in rounded corners, inaccurate critical dimensions, and shorter wire ends
  - \* can use Optical Proximity Correction to fix: basically over-emphasize all the features, and/or add extra lines at outset

# MOS transitive *I-V* Characteristics and **Parasitics**

- *I-V*: current-voltage relationship
- Transistors are not really ideal switches, they have 3 zones of operation: cutoff, linear, saturation
- definitions:

 $V_{gs}$ : voltage gate to source  $V_{gd}$ : voltage gate to drain

 $V_{ds}$ : voltage source to drain (across the channel)  $V_t$ : critical voltage at which transistor is saturated channel: space between the source and drain, where the electrons flow

- remember that the gate is insulated from the area under it by a thin layer of Silicon Dioxide (SiO<sub>2</sub>)
- by convention, the source is the terminal at lower voltage
- cutoff:
- \* when  $V_{qs} < 0$
- \* electrons on the gate attract positive voids in the silicon below, and inhibit current flow. Therefore, the transistor is closed.
- $* I_{ds} = 0$
- linear:
- \*  $V_{gs} > V_t, V_{gd} = V_{gs}, V_{ds} = 0$  or  $V_{gs} > V_t, V_{gs} > V_{gd} > V_t, 0 < V_{ds} < V_{gs} V_t$
- \*  $I_{ds}$  linearly proportional to  $V_{ds}$
- \* channel of electrons forms, allowing current to flow

- \*  $V_{gs} > V_t, V_{gd} < V_t, V_{ds} > V_{gs} V_t$  \* channel pinches off due to electrons attracting to
- \*  $I_{ds}$  is independent of  $V_{ds}$

# capacitor effect

• gate and channel can have a parallel plate capacitor effect, with the thin layer of SiO<sub>2</sub> acting as the insulator

•  $C = \frac{Q}{V} = \epsilon_{SiO_2} wl/t_{SiO_2}, V = V + gc - V_t =$  $(v_{qs} - Vds/2) - V_t$ 

\* l, w: length, width of section of gate above channel

\*  $\epsilon_{SiO_2}$ : permittivity of SiO<sub>2</sub> layer

\*  $t_{SiO_2}$ : thickness of SiO<sub>2</sub> layer

• general capacitance per unit area:  $C_{ox} = \frac{\epsilon_{ox}}{t_{ox}}$ 

\*  $\epsilon_{ox}$ : permittivity of oxidation layer

\*  $t_{ox}$ : thickness of oxidation layer

• carrier velocity: velocity of the electrons?

\* proportional to the electric field running horizontally between source and drain

 $v = \mu E, E = V_{ds}/L, t = L/v = L/(\mu E) = L/(\mu \frac{V_{ds}}{L})$  $\mu$ : mobility. electrons move about twice as fast as positive voids

L: length of channel

- actual velocity of electrons is the speed of light, but they don't travel in a straight line, they travel atom-to-atom
- \* this slowdown is called the **scattering** effect

# Shockley model of transistor

- $V_{dsat} = V_{qs} V_t$
- 1st order model:  $\beta = \mu C_{SiO_2} \frac{w}{I}$

 $I_{ds} = 0$  $V_{qs} < V_t$ cutoff  $V_{ds} < V_{dsat}$   $I_{ds} = \beta (V_{gs} - V_t - \frac{V_{ds}}{2})V_{ds}$   $V_{ds} > V_{dsat}$   $I_{ds} = \frac{\beta}{2}(V_{gs} - V_t)^2$ linear saturation

• Must be able to derive this model on exam!

# Non-Ideal I-V Effects

- velocity saturation (due to scattering)
- \* also called short channel effect
- \* this is hard to make into a mathematical formula
- sub-threshold leakage, junction leakage, gate tunneling

## • Body Effect

\* affected by  $V_{sb}$ : voltage of the p-substrate (which should be ground)

\*  $V_t = V_{t0} + \lambda(\sqrt{|-2\phi_F + V_{sb}|} - \sqrt{|-2\phi_F|})$ -  $V_{t0}$ : threshold without body bias

-  $\phi_F$ : Fermi potential

· negative for nMOS, positive for pMOS

-  $\lambda$ : body effect coefficient

· positive for nMOS, negative for pMOS (reversed)

\* generally fixed/caused by biasing

\* Forward Body Bias (FBB):

 $-V_{sb} < 0, V_t < V_{s0}$ 

- gates switch faster, but leak more current

\* Reverse Body Bias (RBB):

-  $V_{sb} > 0, V_t > V_{s0}$ 

- gates switch slower, but consume less power (because less leakage)

## • Temperature

- \* higher temperature means higher electron mobility, more leakage, and threshold decreases
- Diffusion Capacitance
- \* capacitance on the source/drain:  $C_{sb}$ ,  $C_{db}$
- source/drain are diffusion nodes
- C is comparable to  $C_g$  (gate) for connected nodes,  $\frac{1}{2}C_q$  for unconnected
- (depends on process)

- \* this is the capacitance we care most about (because we must fill it every time the gate switches?)
- \* if two capacitors share a source/drain, that reduces diffusion capacitance (reducing this is a good thing)
- \* also, you can remove unconnected diffusion spots

# DC Response

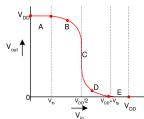

- example: inverter
- must settle to  $I_{dsn} = |I_{dsp}|$
- $V_{tn}$ ,  $V_{tp}$ : threshold voltages for nMOS and pMOS (defined in Non-Ideal *I-V* Effects)
- $V_{in} = V_{DD} \rightarrow V_{out} = 0$ ,  $V_{in} = 0 \rightarrow V_{out} = V_{DD}$

- $$\begin{split} * & V_{gsn} = V_{in}, V_{dsn} = V_{out} \\ * & \text{cutoff: } V_{in} < V_{tn} \\ * & \text{linear: } V_{in} > V_{tn}, V_{out} < V_{in} V_{tn} \\ * & \text{saturated: } V_{in} > V_{tn}, V_{out} > V_{in} V_{tn} \end{split}$$

\*  $V_{gsp} = V_{in} - V_{DD}, V_{dsp} = V_{out} - V_{DD}, T_{tp} < 0$ \* cutoff:  $V_{in} > V_{DD} + V_{tp}$ \* linear:  $V_{in} < V_{DD} + V_{tp}, V_{out} > V_{in} - V_{tp}$ \* saturated:  $V_{in} < V_{DD} + V_{tp}, V_{out} < V_{in} - V_{tp}$ • to calculate actual output voltage, balance  $I_{dsn} = I_{dsp}$ (easiest to do graphically)

\* end up with a graph of  $V_{out}$  as function of  $V_{in}$ 

	0 1	0 000
Region	nMOS	pMOS
Α	Cutoff	Linear
В	Saturation	Linear
С	Saturation	Saturation
D	Linear	Saturation
E	Linear	Cutoff

- \* don't want to switch nMOS and pMOS because then nMOS would saturate at far end of graph (and vice versa for pMOS)
- \* horizontal position of graph can be varied by tuning  $\beta_p/\beta_n$
- called beta ratio, or skewed gate
- $-\beta_p/\beta_n > 1 \to \text{right}, \beta_p/\beta_n \to \text{left}$
- \* unity gain slope: part of response graph where the
- want to tune  $\beta_p/\beta_n$  to put logic levels at these regions to maximize noise margins
- \* Noise Margins:
- $NM_H = |V_{OH} V_{IH}|, NM_L = |V_{OL} V_{IL}|$
- that's just the higher/lower of the two axes

# Transient Analysis

- for instance, find step response of gate to determine
- rise/fall delay: time from when  $V_{in}$  crosses  $\frac{V_{DD}}{2}$  to when  $V_{out}$  crosses it
- rise/fall time: (of  $V_{in}$  or  $V_{out}$ ): time for that signal to go from  $0.1V_{DD}$  to  $0.9V_{DD}$  (or reverse)
- TODO many equations and such for inverter step response (from slides)
- TODO pass transistors (form slides)

# Pass Transistors

- for nMOS trying to pass  $V_{DD}$  or pMOS trying to pass 0
- nMOS can pull no higher than  $V_{DD} V_{tn}$  if  $V_q = V_{DD}$
- \* more generally,  $V_g V_{tn}$ \* called degraded 1
- pMOS can pull no lower than  $|V_{tp}|$

- generally estimated with RC models
- \* for nMOS with width k:
- \* resistance of R/k

- \* caps of kC on all terminals
- \* pMOS same except resistance is 2R/k
- $\bullet$  depends on effective R and C of transistors
- \* exactly what parasitic caps depends on exact layout (which stuff is shared between transistors)
- \* C proportional to width (approx 2 fF/ $\mu$ m)
- \* R inversely proportional to width (approx  $6k\Omega^*\mu m$ )
- \* TODO unity transistors
- find widths necessary for rise and fall resistance to be same as standard inverter
- \* pMOS is about half as conductive as nMOS, so the inverter has nMOS=1, pMOS=2
- \* larger width  $\rightarrow$  smaller R
- \* transistors in series: delay adds, so double the width
- \* transistors in parallel: same as a single transistor (because we assume worst case of only one being
- use effective resistance in RC model:  $I_{ds} = V_{ds}/R$  (just good enough for a RC model, not for current at arbitrary time)
- find delay of circuit
- \* decompose to RC model (take into account widths of each transistor)
- replace transistors with resistors
- add parasitic caps on either side of every transistor (cap value = width of transistor)
  - · caps with both pins short to ground don't count, are never charged
- · caps from  $V_{DD}$  to ground don't count, always charged
- \* add together all R and C's to get delay
- don't count R of nMOS and pMOS at the same time, because they're never on at the same time
- Delay d = f + p
- Effort Delay  $\hat{f} = gh$
- \* g: logical effort: relative ability of gate to deliver current
- g = 1 for standard inverter
- \* h: electrical effort: ratio of input to output capacitance
- also called fanout
- Parasitic Delay p
- \* independent of load (represents delay of gate driving no load)
- \* set by internal parasitic capacitance
- Elmore Delay:
- \* ON transistors look like resistors, so pullup/pulldown network is modeled as RC ladder
- \*  $t = \sum_{i \in nodes} R_{i-to-source} C_i$
- =  $R_1C_1 + (R_1 + R_2)C_2 + \ldots + (R_1 + \ldots + R_n)C_n$  Ideal number of stages for inverter driving large load
- \* delay =  $\left(\frac{C_{load}}{C_{inv}}\right)^{\frac{1}{k}} kR_{inv}C_{inv}$ \* k: number of stages
- \* stage size ratio:  $\left(\frac{C_{load}}{C_{inv}}\right)^{\frac{1}{k}}$

# Static Timing Analysis

- worst case at each step
- in form arrival time / required arrival time / slack
- arrival time: input to output, take max
- required arrival time: output to input, take min
- \* work backward
- \* if a gate drives only one gate on it's output, this is
- slack: required arrival time arrival time
- Contamination delay: just best case delay (smallest delay)

- \* in this case, you'll count parallel transistors as parallel resistors
- not sure about this stuff, Peter just said to not worry about this question on the homework

#### Power Estimation

- Dynamic Power
- \* power required to charge the load capacitor
- \* only counted when transistor switches
- therefore this power usage is data dependent
- therefore, you have to count the falling transitions in the output per time period
- \*  $P_{dynamic} = \frac{1}{T} \int_0^T i_{DD}(t) V_{DD} dt$ \* for any gate:  $P_{dynamic} = CV_{DD}^2 f_{sw}$  Activity Factor  $\alpha$

- \*  $\alpha$ : how often this gate switches in terms of the base clock frequency
- \*  $\alpha = 1$ : clock;  $\alpha = 0.5$ : every other cycle, etc...
- \* for system clock at frequency f,  $P_{dynamic} = \alpha C V_{DD}^2 f$
- Short Circuit Current
- \* nMOS and pMOS may both be on for a short instant during switching, leading to a short instant of short circuit current (from  $V_{DD}$  to ground)
- \*  $P_s \propto (V_{DD} 2V_t)^3 t_r f_p$ assume  $t_r = t_f$  for input  $f_p$ : frequency of input
- \* this is less than 10% of dynamic power if the rise/fall times are comparable
- Static Power
- \* leakage when gate is off
  - $I_{ds} = I_{ds0}e^{\frac{V_{gs} V_t}{nv_T}} \left(1 e^{\frac{-V_{ds}}{v_T}}\right)$  $V_t = V_{t0} - \eta V_{ds} + \gamma \left( \sqrt{\phi_s + V_{sb}} - \sqrt{\phi_s} \right)$

# After exam 1

- exam 1 was on March 8 (2017.03.08)
- nothing specifically from previous exam

## Propagation vs Contamination delay

- contamination delay  $(t_{cd})$ : time from input change to any output changing value
  - \* kind of a best-case delay or smallest possible delay
  - \* time counted when input crosses 50% of logical high voltage level
- propagation delay: time from when all inputs are stable to when all outputs are stable
- \* kind of like a worst-case delay

#### Latch vs Flip Flop

- Latch is level-sensitive, flip-flop is edge-sensitive
- register is flip-flop

### Latch/flip flop designs

- pass transistor latch
- \* pros: tiny, low clock load
- \* con: voltage drop across is  $V_t$ , it's non-restoring
- \* con: not really a latch because doesn't hold signal
- transmission gate
- \* pro: no  $V_t$  drop
- \* con: requires inverted clock
- inverting buffer
- \* TODO
- tristate feedback
- \* first complete latch here
- \* risk of backdriving: downstream could change state if it is very strong
- buffered output
- \* no backdrifing problem
- \* widely used

- \* rather large and slow though, and large load on clock
- a flip-flop is just two latches back-to-back

# Metastability

- stable works if it's not at a strong high or low but will settle somewhere
- metastable is where it might sit there, but if it must settle, you don't know which one it will settle to when perturbed

# Sequential Circuits

- sequential means that the circuit holds state: the output depends on both current and past input
- to model a state machine, you can unroll it to [regieter]
  → [combinational] → ...
- \* this way you can use regular timing stuff for it: arrival time, slack, etc...
- Mealy FSM: output of circuit is from combinational logic
- Moore FSM: output is from registers
- pipelined circuit: uses registers to hold state between clock cycles, because not all of the combinational logic can happen fast enough to work in a single clock cycle \* pipelined circuits can use flip-flops or latches?
- the clock consumes 20-30% of the power on a chip
- the whole reason that registers are needed is because data (signals) moves through components at non-constant speed
- reset
- \* can be sync or async
- \* force low output when reset is high
- sequencing: it is (generally) equivalent to split the sequential logic in two, and then use two latches (one halfway through) instead of one large section of sequential logic with flip-flops at either end
- \* this is called two phase clocking
- \* you have to make sure the middle latch operates on clock-bar instead of clock
- timing:

 $\begin{array}{ll} t_{pd} & \text{logic propagation delay} \\ t_{cd} & \text{logic contamination delay} \\ t_{pcq} & \text{Clk} \rightarrow \text{Q} \text{ propagation delay} \\ t_{ccq} & \text{Clk} \rightarrow \text{Q} \text{ contamination delay} \\ t_{pdq} & \text{D} \rightarrow \text{Q} \text{ propagation delay} \\ t_{setup} & \text{setup time of flip-flop/latch} \\ t_{hold} & \text{hold time of flip-flop/latch} \end{array}$ 

- \*  $D\rightarrow Q$  delay only makes sense for latches, since for flip-flops it is simply one clock cycle
- sequencing overhead and max delay:
- \*  $T_c$ : cycle time
- \* need for combinational logic to be fast enough
- \* for single phase flip flop:  $\bar{t}_{pd} < T_c (T_{setup} + T_{pcq})$
- \* for two-phase latch:  $t_{pd} = t_{pd1} + t_{pd2} < T_c 2t_{pdq}$
- \* max delay is dictated by cycle time and sequencing overhead; sequencing overhead does not effect minimum delay
- minimum delay:
- \* for single phase flip flop:  $t_{cd} > t_{hold} t_{ccq}$
- combinational stuff must be slow enough that it doesn't violate hold time of second flip flop
- \* for two-phase latch:
- $t_{cd1}, t_{cd2} > t_{hold} t_{ccq} t_{non-overlap}$
- hold time applies twice each cycle, once per each combinational circuit
- $t_{non-overlap}$ : phase between clock signals?
- time borrowing: for two-phase latch-based system, you can borrow time from one segment to the other while the latch is transparent
- \* works (is possible) as long as the total circuit still completes within one clock cycle

- clock skew:
  - \* when uncertain: causes tighter required CL propagation delay and minimum CL contamination delay, and reduces opportunity for time borrowing.
- \* when know constant skew: can help with same effect as time borrowing, except can also have effect for flip-flop based systems
- if setup times are violated, you can reduce clock speed to fix it
- if hold times are violated, it won't work at any clock speed

# Clocking

#### •

# Wire Delay

• n-segment  $\pi$  model: to model, find total R and C of wire; then split up according to n segment model, then combine adjacent

## Miller Effect

- AKA crosstalk; it's when one wire affects another
- it's dynamic; depends on what signal the wires are carrying
- MCF: Miller factor (or something)
- for two wires A and B, model as

- 101 0110	, ,, 11 co 11 co11 co 12 .			
$C_{eff} = C_{qnd} + MCF \cdot C_{adj}$				
	behavior of B	MCF		
• MCF:	constant	1		
• MCF:	with A	0		
	opposite A	2		

# **Timing**

- setup time: minimum time that signal must remain stead **before** clock edge
- hold time: minimum time that signal must remain stead **after** clock edge
- propagation delay: when driving another gate? largest (worst case) delay?
- contamination delay: best case delay (smallest delay)?
- parasitic delay: independent of load
- effort delay: proportional to load capacitance (nothing to do with the thing that is doing the driving of the load capacitance)
- maximum possible logic propagation delay for combinational circuit buffered on either side by flip-flops: clockCycle Clk $\rightarrow$ Q FlipFlopSetup WorstSkew
- \* minimum circuit delay: HoldTime Clk→Q

#### Memory

- serial access memory (SAM): accessed in a sequence, not randomly
- \* ex. shift register, queue, stack, etc...
- \* often implemented using random access memory
- Shift Register
- \* serial in, parallel out
- \* large number of transistors per cell when implemented using flip flop
- \* tapped delay line: shift register with variable number of stages
- useful for allowing chips at different clock frequencies to communicate (apparently)
- queue or stack can be built using SRAM block with pointers to first/last and stuff
- SRAM
- \* static ram
- \* can be dual ported: means you can write to a cell while reading the old value from it
- \* designed in a cell grid, MUXes for input and then decoders for output connected to bit lines that run across the cells

- \* TODO note about pre charging bit line
- DRAM
- \* stores bits using capacitors
- decoders
  - \* needed to switch to the right bit-line
  - \* need to be pitch-matched to RAM cell width for efficiency
  - \* TODO note about twisted bit lines
- ROM: read only memory
- \* used to be custom masked chips for data
- \*

## • PROM

# Packaging

- flip chip: put connection pads on the surface of the die instead of the edges
- \* then flip the chip over and affix it directly to the package
- \* means the die must be positioned in the package more precisely
- Heat
- \* Thermal Resistance:  $\Delta T = \theta_{iaa} P$
- $\Delta T$ : temperature rise in chip
- $\theta_{ja}$ : thermal resistance of chip junction to ambient; units: C/W
- P: power dissipation on chip
- IO
- \* ESD Protection: TODO
- \* output pads:
- must drive large off-chip loads (2-50pF) do that using successively larger buffers
- surround with guard ring to protect against lockup
- \* input pads:
- may need level converters
- Schmitt trigger: allow signal to cross high/low edge only after it goes a little over the tipping point
- \* bidirectional pads:
- combine input and output
- use tristate driver to set pin direction
- \* analog:
- no buffering
- any protection circuitry must be careful to not distort the signal at all
- RF pads?
